ABSTRACT

From the 1.4 GHz radio survey of Condon, Dickey, & Salpeter (1990) in a region much devoid of rich galaxy clusters at redshifts $z \lesssim 0.4$, we selected a “distant” sample of 57 radio sources complete to a 1.4 GHz flux density of 35 mJy and a “nearby” sample of 36 mostly weaker radio sources which are optically brighter than $B \sim 19$ mag. Our ultimate goals are (1) to study the radio, optical and near-IR properties of those high-redshift ($z \sim 1$), moderate-power radio sources in the distant sample and to compare them with that of more powerful radio sources, and (2) to make a comparison of primarily non-cluster radio sources in the nearby sample with a companion survey of radio sources in a pair of rich superclusters at $z \sim 0.1$. In this first paper of a series, we report our new C-array VLA continuum snapshots at 4.86 GHz and optical R-band CCD imaging photometry for these two samples and tabulate the observational results on individual sources.

Some direct sample statistical properties are also discussed in the paper and summarized as follows: (1) The distant sample: (a) The sample median flux density at 1.4 GHz is about 65 mJy. (b) The majority (80%) of the sample sources have a steep spectrum between 1.4 and 4.86 GHz with a spectral index around 0.9. Nineteen (90%) of the 21 sources that are *fully* resolved at 4.86 GHz (i.e., angular sizes $\theta \gtrsim 11''$) have a radio morphology of Fanaroff-Riley (FR) II type. (c) Thirty-seven (88%) of the 42 optically imaged sample sources were optically identified to a limiting R-band magnitude of $R \sim 23.5$ mag. About 15% of the identified radio sources appear to be point sources and the others are extended galaxies with an appearance similar to nearby elliptical galaxies. (d) Twenty-eight (76%) of the optically identified sources have $R > 20$ mag, suggesting that these are probably distant ($z \gtrsim 0.8$), with a redshift distribution

peaking at $z \sim 1$ where their radio luminosities are about 10 times the break power between the FR I and II classes. (e) We found no strong evidence for the radio and optical axes of the resolved radio sources (i.e., $\theta \gtrsim 5''$) to be correlated or anti-correlated, nor any evidence for strong clustering around sample radio sources on average. (2) The nearby sample: Except for $R \lesssim 15$, the sample is dominated by elliptical galaxies with $16 \lesssim R < 18.5$ mag and a spectral index distribution similar to that of the distant sample. Based on the radial distribution of optical objects around each radio source, we found that the average radio source environment becomes richer from that characteristic of galaxy groups for $R < 17$ mag ($z \lesssim 0.2$) to that of galaxy groups to clusters at $R \gtrsim 18$ mag ($z \gtrsim 0.3$).

Subject headings: cosmology — galaxies: photometry --- galaxies: distances and redshifts — galaxies: clustering — radio continuum: galaxies --- surveys

1. Introduction

A recent survey using 56 contiguous Very Large Array (VLA)¹ D-array fields (Condon, Dickey, & Salpeter 1990; hereafter CDS90) has yielded a uniform catalog of 354 radio-continuum sources with radio flux densities at 1.4 GHz, $S_{1.4}$, down to about 1.5 mJy in a 12 square degree area at high Galactic latitudes. The area is known to be much devoid of rich Abell clusters below a redshift $z \sim 0.4$ (Gunn, Hoessel & Oke 1986). As explained below, this geometry has several advantages.

Firstly, the general deficiency of galaxies at low redshifts increases the chance for selecting distant radio sources. We are particularly interested in a sample of CDS90 sources complete to $S_{1.4} = 35$ mJy (hereafter referred to as the “distant” sample or 1) S). The break power ($\sim 10^{25}$ W Hz⁻¹ at 1.4 GHz) between the high-power, Fanaroff-Riley type II (FR II-type; Fanaroff & Riley 1974) and low-power, FR I-type radio sources corresponds to $S_{1.4} \approx 10$ mJy at $z \sim 1$. The above distant sample, at $z \sim 1$, explores moderate-power, typical FR II-type radio sources; and therefore it extends the extensively studied 3CR radio catalog ($\gtrsim 1500$ mJy at 1.4 GHz; Spinrad et al. 1985) and the so-called 1-Jy sample ($\gtrsim 400$ mJy at 1.4 GHz; Allington-Smith 1982). One motivation in constructing such a mJy radio sample is to address the fundamental question of how the dramatic optical, near-IR and radio evolution of radio galaxies from the present to $z \sim 1$ (e.g., Lilly & Longair 1984; McCarthy et al. 1987; Le Fevre & Hammer 1988; Eisenhardt & Chokshi 1990; Rigler et al. 1992; McCarthy 1993 and references therein) depends on radio power and redshift. This question arises because the most detailed studies, including those cited above, were based primarily on the powerful 3CR radio sources which show a strong correlation between radio

¹The Very Large Array (VLA) is a facility of the National Radio Astronomy Observatory operated by Associated Universities, Inc., under cooperative agreement with the National Science Foundation.

luminosity and redshift (McCarthy 1988). Some recent studies on fainter radio sources at high redshifts (Dunlop & Peacock 1993; Owen & Keel 1995) have shown some indications of a radio-luminosity dependence of radio source evolution between $z \sim 1$ and the present. The distant sample studied in this paper is about 45 times fainter than the 3CR, and with appropriate redshift and photometric data it is ideal for addressing the above question.

Using $S_\nu \propto \nu^{-0.9}$ to compare intensities at different frequencies, our distant sample is ~ 8 times fainter than the 1-Jy sample of Allington-Smith (1982) or the similarly bright, but less completely identified 4C sample (Pilkington & Scott 1965), MRC/1-Jy survey (McCarthy et al. 1990) and Parkes Survey (Wright, Savage, & Bolton 1977). The existing samples comparable to ours in flux are the B3 survey (Ficarra, Grueff, & Tomassetti 1985) and the Texas surveys (Bozyan 1992). However, their optical identifications are quite incomplete yet. The deeper 5C 12 sample (Eisenstein et al. 1982) and sub-millijansky sample of Windhorst et al. (1984, 1985) are far from completely identified and contain many low-power FR I radio sources even for $z \gtrsim 1$.

Our second interest lies in the fact that most of the CDS90 radio sources at redshifts below $z \sim 0.4$ are of FR I-type and in non-cluster environments. By scanning a Palomar Observatory Sky Survey (POSS) plate, CDS90 generated a catalog of optical galaxies down to $B \sim 19$ mag. This led to optical identifications of most of the radio sources with $z \lesssim 0.3$ (i.e., Table IV of CDS90). Using the same optical catalog of galaxies, CDS90 found some evidence for clustering over small scales (of that of galaxy groups or 100SC clusters) around these radio sources. Although it has been known that FR I-type radio sources apparently tend to live in rich clusters (e.g., Longair & Seldner 1979), an interesting question is whether the current radio activities depend more on their immediate environments (say, over scales of galaxy groups), than on environments over a much larger scale (say, over scales of galaxy clusters or superclusters). One approach to this question is to study the local environments

of radio sources of similar powers, but in quite different environments over a much larger scale. In a future paper we will describe our companion radio survey, similar to CDS90, but in a direction towards two of the richest superclusters (R.A. $\sim 15^{\text{h}}20^{\text{m}}$, decl. $\sim 29^{\circ}$; $z \sim 0.1$; see Bahcall & Soncira 1984a, and Batuski & Burns 1985) in the local universe and will make a comparison between it and the sample of nearby CDS90 radio sources. In the current paper we study a sample of nearby radio sources from CDS90 with $B \lesssim 19$ mag (hereafter, referred to as the “nearby” sample or NS).

Spectroscopic redshift data on most NS sources and some DS sources have been obtained and will be given in subsequent papers, together with some optical color data. In this first paper, we report our new C-array VLA continuum snapshots at 4.86 GHz and optical R-band CCD imaging photometry on the above two samples. The remainder of this paper is organized as follows: We describe our sample selection in §2, VLA radio observations at 4.86 GHz and their results in §3, and optical CCD imaging photometry and radio source identification in §4. Some direct statistics of the distant and nearby samples are discussed in §5 and §6, respectively. Finally, a summary is given in §7.

2. Samples of Radio Sources

The 1.4 GHz radio catalog of CDS90 is confined to the area bounded roughly by $9^{\text{h}}36^{\text{m}} < \alpha < 9^{\text{h}}55^{\text{m}}$ and $46^{\circ}6' < \delta < 48^{\circ}30'$ (centered at about 47° in Galactic latitude) and is fairly complete to a flux density of 3 mJy at 1.4 GHz. The two radio samples in the current paper are selected from their catalog as follows:

After excluding two sources with a primary VLA beam correction greater than 5 (R001 and R002 in their Table 11), the remaining 56 radio sources with an integrated flux density at 1.4 GHz, $S_{1.4}$, greater than 35 mJy in CDS90 constitute our distant sample. Fig. 1

shows the integral distribution of the DS sources as a function of $S_{1.4}$, illustrating a good completeness down to $S_{1.4} = 35$ mJy. The median value of $S_{1.4}$ for this sample is about 65 mJy.

Using a catalog of optical galaxies down to $B \sim 19$ mag that was generated by scanning the appropriate 1'0SS plate, CDS90 optically identified 58 of their radio sources with $\delta\theta \leq 15''$, where SO is the separation between the 1.4 GHz position of the radio source and the optical counterpart, defined to be the nearest object in their optical galaxy catalog. These are primarily nearby ($z \lesssim 0.3$), low-power radio sources and are listed in their Tables IV(a) and IV(b). Our nearby radio sample (or NS) contains those 36 sources with $\delta\theta \lesssim 10''$, including two (R133 and IWO) that have a large enough radio flux to also be in the distant sample.

We also managed to obtain VLA C-array snapshots at 4.86 GHz and some optical CCD imaging photometry for 8 additional radio sources of which R195 and R231, together with the other three (R082, R191, and R252) that are already in our nearby sample, lie within $40''$ on the sky of some Abell-like clusters (likely at $z \gtrsim 0.4$) in Gunn et al. (1986). The CCD fields of these sources are used in §5 and §6 as references to study the environments of our DS and NS radio sources. All of the forenamed radio sources are listed in Table 2, to be explained in the next section.

3. VLA Continuum Snapshots at 4.86 GHz and Compilation of Radio Data

3.1. VLA Snapshots, Data Reduction and Results

In order to obtain better positions, radio spectral indices and morphological data, radio-continuum snapshots at 4.86 GHz ($\lambda \approx 6$ cm) were obtained for all but two sources (R262 and R353) in the distant sample, 18 sources in the nearby sample and all the

additional radio sources described in §2. The snapshots, centered on the 1.4 GHz positions from CDS90, were taken in a single 8 hour session on 1990 December 1 with the VLA in its C configuration. Each source was observed for 5 minutes with a 50 MHz bandpass. Phase calibration was performed using the source 0920+446 (J2000) from the standard VLA calibrator list, and fluxes were calibrated against both 3C 48 and 3C 286. The resulting synthesized (FWHM) beam is about $4''.2$. The data were “CLEANed” and corrected for primary beam response using standard routines in the AIPS software package of National Radio Astronomy Observatory. Cleaning reached the expected radiometer noise of 0.15 mJy/beam or so for all but the brightest 2 to 3 sources. Source parameters were measured using the AIPS task IMFIT to fit Gaussian functions to the individual components of each source.

The 4.86GHz contour maps are shown in Fig. 2. We give in Table 1 some derived parameters for each radio ‘signal’ detected on these radio maps, organized in column (1) by the source names taken from CDS90. In the fields of R147 and R202, the detected signals appear to contain two independent radio sources: in addition to a well defined, bright FR II-type radio source near the 1.4 GHz position, there is a weaker radio signal away from the map center. For these cases, the brighter source was taken to be our radio source while the weaker one is noted by suffixing a letter “n” (for ‘near’) to its name in Table 1. The remaining columns of Table 1 are as follows: Columns (2) and (3) are, respectively, the right ascension and declination (in the format of “hhmmss.ss” and “ddmmss.s”, respectively; equinox 1950) for each detected signal. These are the peak position of the best-fit Gaussian profile to each signal. The typical rms positional error is of $< 0''.3$ for unresolved signals and is somewhat larger for resolved sources. Columns (4) and (5) give, respectively, the peak and integrated flux densities in mJy. Columns (6) and (7) are, respectively, the estimated major and minor axes of each detected source in units of arcseconds if these are obtainable. Finally, column (8) gives the position angle (north to east of the major axis) in degrees.

The numbers appearing in parentheses in columns (4) to (8) are the estimated rms errors,

3.2. Compilation of the Radio Data

Table 2 is a complete list of the radio sources in tile two samples plus the few additional sources. We tabulated here the following integral parameters by combining Table 1 in this paper and the 1.4 GHz radio survey of CDS90: Column (2) indicates to which sample a radio source belongs to, where "DS" and "NS" represent the distant and nearby samples, respectively, and 'a' denotes an additional source. Columns (3) and (4) are the right ascension and declination (equinox 1950) of the adopted center of each radio source. Unless a source was not observed at 4.86 GHz in this paper for which the 1.4 GHz position taken from CDS90 was quoted, the position was determined from the 4.86GHz C-array radio map using the following rule: for a radio source showing only one component, this position is the peak position from the Gaussian fitting, i.e., that given in columns (2) and (3) of Table 1; for a double-lobed source with a detected core, the core peak position is used; for a double-lobed source without a detected core, the mean position of the two radio lobes is usually used; and for a source of more than 3 components, the average position of all the components is usually given here. Columns (5) and (6) list the integrated flux densities in mJy at 1.4 and 4.86 GHz, respectively. Column (7) gives the spectral index, α , between the frequencies 1.4 and 4.86 GHz. This was derived from the flux densities in the previous two columns assuming $S_\nu \propto \nu^{-\alpha}$. Column (8) gives θ , the (maximum) angular size in units of arcseconds from the 4.86GHz radio map. For unresolved and single-component sources, this is simply the major axis (or its upper limit) given in column (6) of Table 1; for double-lobed sources, this was taken to be the separation between the peaks of the two radio lobes; and for a few sources with more than 3 components, this is the estimated maximum angular extent of the source. Column (9) gives the position angle (north to east) in degrees

of the major axis for single-component sources or of the axis connecting the two radio lobes for double-lobed sources. Finally, in column (10) we give a very brief morphological description, where FR I and FR II morphology, assigned only to *fully* resolved sources (i.e., $\theta \gtrsim 11'' \approx 2.5$ times the VLA beam), was determined as in Fanaroff & Riley (1974); namely, the ratio of the separation between the peaks in the brightness distribution of each lobe to that between the outermost contours on opposite sides of the source is measured. FR I or FR II is assigned if this ratio is less or greater than 0.5.

Two DS sources (R182 and R307) and one NS source (R203) likely contain two independent radio sources each, based on their radio morphology and probable optical identifications (see the next section). We have simply divided the total 1.4 GHz flux density between the two independent components in proportion to their 4.86 GHz flux densities and identified each of them in Table 2 by a suffix of "A" or "B" to its name. As a result R307A from the DS now has $S_{1.4} < 35$ mJy and R203B was not optically identified (see Table 3). The above two sources were left out of their respective samples. For the remainder of this paper and in Table 2, our DS consists of 57 sources (including R182A, R182B and R307B, but excluding R307A) and our NS still consists of 36 sources (including R203A, but excluding R203B).

4. Optical CCD Imaging Photometry and Radio Source Identification

4.1. Optical Observations and Data Reduction

Optical CCD images in broad R-band, centered on the 1.4 GHz radio positions, were obtained for a total of 59 radio sources, including 42 from the DS, 16 from the NS (including 2 that overlap with the DS) and some additional sources.

The observations were carried out with the 200 inch (5.08m) telescope equipped with

the four-shooter CCD cameras (see Gunn et al. 1987 for a description of this instrument) at Palomar Observatory² during nights of (UT) 1990 February 24, 26, and 27 and April 27 and 28 and of 1991 January 18 to 20 in 1991. The final CCD images have a field of about 4.2' x 4.2' and a scale of 0".336 per pixel. For our primary imaging it-band, we used a Gunn *r* filter that centers at $\lambda_0 \sim 6650 \text{ \AA}$ and that mimics the Cousins-R filter (Cousins 1976). The integration time per field was 600 seconds per source except for R042. Additional V- and I-band images were also obtained for a large fraction of the sources observed in R and the resulting colors will be present in a subsequent paper. During each observing night, a few standard stars from Landolt (1983) and/or stars in the field of M67 (Schild 1983) were observed over a wide range of air masses for the purpose of flux calibration. The weather condition was not quite photometric for part of the nights of (UT) 1990 February 24 and 1991 January 17. The seeing varied (1".2 to greater than 2") over the course of our run. Therefore, we give in Table 3 (to be explained below), for each image, its date of observation and optical seeing.

Each CCD image was reduced in the conventional way: The zero-level bias was determined by fitting a polynomial to an overscan exposure and was subsequently removed from the whole CCD frame. The flattening was done using a skyflat generated by median-filtering a number of 'sky' exposures. The resulting background is flat within about 0.5% for most frames.

²Observations at the Palomar Observatory were made as part of a continuing collaborative agreement between the California Institute of Technology and Cornell University.

4.2. Detections, Catalogs and Photometry of Optical Objects

Objects on each CCD image were detected and their various photometric parameters were evaluated using the Faint Object Classification and Analysis System (hereafter referred to as FOCAS; Valdes 1982, see also Jarvis & Tyson 1981) provided by National Optical Astronomy Observatories. The procedure is described briefly below:

Object detection: The FOCAS detected any object whose area, A_{iso} , is larger than a predetermined minimum area A_{min} , where A_{iso} is made of the contiguous pixels whose values are more than k times the rms sky noise (σ) above the local sky level. We used $k = 2.5$ as recommended by Valdes (1982). The optimal value of A_{min} depends on the optical seeing. We used a conservative value of $A_{\text{min}} = 10 \text{ pixel}^2$ (or 1.1 arcsec^2). However, below $A \lesssim 20 \text{ pixels}^2$, a significant fraction of detections were found to be spurious. We also used in our detection process the FOCAS built-in filter of 5×5 pixels (Valdes 1982) that increases the S/N ratio.

Photometry: For a detected object, the FOCAS further elaborated the local sky value by analyzing the pixels around that object, and an isophotal magnitude, R_{iso} , was evaluated by summing up the sky-subtracted pixels within the area A_{iso} . R_{iso} was found to be, on average, equivalent to the isophotal magnitude at a surface brightness of $\mu_R \sim 30 \text{ mag arcsec}^{-2}$. At this faint isophote, R_{iso} essentially measures the total magnitude and the effect of varying optical seeings on the value of R_{iso} is small. A second magnitude, R_{tot} , was also evaluated by summing up the pixels within an aperture whose area is $2A_{\text{iso}}$. We will use this aperture magnitude below to define, in a consistent way, the isophotal magnitudes of overlapped objects.

Geometry: The pixels within the area A_{iso} were also used to obtain various simple and luminosity-weighted moments which we used to determine the diameters, ellipticity and position angle of an object.

Overlapped Objects: Overlapped objects were separated as follows: First, FOCAS raised the intensity threshold for detection by 0.2 times the sky sigma, then it ran the same detector for detecting objects with areas larger than A_{\min} . If two or more objects were detected, the original object (parent) was split into individual objects (daughters) and each of the daughter objects was subject to further splitting if the level of this splitting loop was less than N_s , a predetermined quantity. For each split object, the total magnitude was not evaluated directly. Instead the total luminosity of the parent object was divided between daughter objects in proportion to their isophotal luminosities. To avoid a large number of spurious splits around bright objects, we used $N_s = 5$. This usually gave satisfactory results except for highly overlapped binaries or galaxies in very crowded regions. We found that such a splitting usually increases the number of objects by 5% to 15% for $R \lesssim 24$ mag.

For a split object, we defined its isophotal magnitude and area in the following self-consistent way:

$$R_{\text{iso}}^i = R_{\text{iso}}^p + (R_{\text{tot}}^i - R_{\text{tot}}^p), \quad (1)$$

and

$$A_{\text{iso}}^i = A_{\text{iso}}^p (A_{\text{iso}}^i / \sum_j A_{\text{iso}}^j), \quad (2)$$

where the superscript "i" stands for the i^{th} daughter object, the superscript "p" stands for its parent object, and the sum in eq. (2) was evaluated over all the daughter objects of the same parent. The input isophotal parameters on the right-hand side of eq. (2) are those given by the FOCAS. For multiple-level splits, eqs. (1) and (2) were calculated from the top, single parent object down to each final split object.

Statistics of a typical optical catalog are illustrated in Fig. 3 using the representative CCD field of R035 with an optical seeing of $\sim 1''.5$ (FWHM). Fig. 3a shows the distribution of the isophotal magnitudes of 545 originally detected objects (the solid squares). No attempt has been made in Fig. 3 to separate galaxies from stars. We plot by the dashed

curve the expected counts for our CCD field from field galaxies and Galactic stars. This curve was built using the R-band galaxy counts of Tyson (1988) and the V-band star counts of Bahcall & Soneira (1984b) that were converted to the R-band by assuming $(V - R) = 0.4$ mag. Since the radio source field is at high Galactic latitude ($b \sim 470$), no latitude correction was applied in converting the star counts of Bahcall & Soneira (towards the northern Galactic pole) to our CCD fields. It is gratifying to see that up to $R_{\text{iso}} \sim 24$ mag the data points follow the curve fairly well, suggesting that our optical catalogs are complete to about $R_{\text{iso}} \gtrsim 23.5$ mag. Fig. 3b plots R_{iso} versus R_{tot} for all the detected objects. It shows that the average systematic difference between R_{iso} and R_{tot} is always smaller than 0.3 mag for $R \lesssim 24$ mag. The measurement errors of R_{iso} are dominated by the uncertainty of the sky value. A comparison between the magnitudes obtained with a local sky value and those obtained using a global sky value indicates that the measurement errors are on the order of 0.3 mag for $R \sim 24$ mag. We therefore believe that R_{iso} measures the total magnitude within an accuracy of 0.5 mag at $R \sim 24$ mag. The mean isophotal area, A_{iso} is about 35 pixels² (or 4 arcsec²) at $R_{\text{iso}} \approx 24$ as shown in Fig. 3c which plots the isophotal area in units of square pixels (1 pixel = 0".336) versus R_{iso} for the originally detected objects. Fig. 3 changed little if the objects after FOCAS splitting with $N_s = 5$ were used instead. In the remainder of this paper, we shall use R_{iso} only (and leave out its subscript for simplicity), truncate each optical catalog at $R \sim 23.5$ mag, and refer the number of objects (with $R \lesssim 23.5$ mag) in an optical catalog as $N^{23.5}_{\text{opt}}$.

Both optical seeing and weather conditions could have some effect on the completeness of an optical catalog. This is illustrated in Fig. 4, a plot of $N^{23.5}_{\text{opt}}$ as a function of the FWHM of the optical seeing. We have used circles for the DS sources and squares for the NS and additional sources. The 5 sources that are close to some known galaxy clusters (cf. §1) have their square symbols darkened (one of them, R082, with $N^{23.5}_{\text{opt}} = 453$ and an optical seeing of 1".6, is off the scale), as do the 5 DS sources that are not optically

identified in this paper (see §4.3 below). The figure indicates that the optical seeing starts to affect the completeness of an optical catalog when it becomes greater than $\sim 2''$. Although the CCD fields of the 5 DS sources that are not optically identified in this paper have a moderate optical seeing ($1''.4$ to $2''.4$), all but one (RJ 47) have relatively low values of $N^{23.5}_{\text{opt}}$. The majority of the CCD fields with $N^{23.5}_{\text{opt}} \lesssim 150$ were obtained on the night of UT 24 February 1990 or 18 January 1991, both of which had periods of unstable weather. It is, therefore, plausible that at least some of the optically unidentified DS sources may actually be brighter than our detection limit. Those CCD fields with $N^{23.5}_{\text{opt}} \lesssim 150$ will not be used in our statistical analysis in §5 and §6.

4.3. Optical Identification of Radio Sources

4.3.1. Astrometry

Astrometry was done using two kinds of position calibrators: (1) the Hubble Space Telescope (HST) Guide Star Catalog (GSC; see Lasker et al. 1990 and references therein) and (2) a catalog of fainter stars (down to about $B \sim 19$ mag), generated from scanning the Palomar Sky Survey plate in CDS90. The former has an overall rms positional error of about $0''.5$ (Russell et al. 1990), but contains only relatively bright stars which are sparse over our relatively small CCD fields; while the latter usually provides about 5 to a dozen stars in each CCD field, but has somewhat larger positional errors (see CDS90 or Dickey, Keller, & Bennington 1987). Using the stars common to these two catalogs, we found a systematic offset of $\lesssim 2''$ in both R.A. and decl. between these two catalogs. Since a higher rate of radio source identifications was obtained using astrometry based on the GSC positions than on the stellar positions of CDS90, we have tied the coordinate system of CDS90 to that of the GSC by statistically correcting, in the Appendix, the above systematic offsets. The final rms positional difference between the CGS system and the converted

CDS90 system is about 0".9 in either RA or Dec, in agreement with the statistical errors of these two catalogs. Taking into consideration the external errors of the GSC, we simply adopted a value of 1".0 for the total rms positional error for each calibrator from CDS90.

4.3.2. Definition of Error Ellipses

An optical object detected by the FOCAS as described in §4.2 was regarded to be an identification of the radio source under consideration if the optical object is within the error (or searching) ellipse of the radio source (except for a few sources identified with an optically bright, extended galaxy as noted in 'table 3). For a single-component radio source (including the unresolved ones) or a double-lobed source with a detected radio core, this error ellipse reduces to a circle centered at the position of the radio source (or its core) with a radius given by

$$r_s = 3\sqrt{\sigma_{\text{radio}}^2 + \frac{\sigma_{\text{star}}^2}{N_{\text{star}}}}, \quad (3)$$

where σ_{radio} is the rms positional error in our 4.86 GHz radio data, σ_{star} is the rms positional error for the calibrating stars, and N_{star} is the number of stars used in astrometry. We have adopted the following values: $\sigma_{\text{radio}} \approx 0".3$ and $0".6$ for unresolved and clearly resolved radio sources, respectively; and $\sigma_{\text{star}} \approx 1".0$ as discussed in §4.3.1.

For a double-lobed radio source without a detected core, the most probable position of its optical counterpart is within an ellipse centered at the middle point between the peaks of the two radio lobes and being elongated along the radio axis as shown by Laing, Riley & Longair (1983). Following their results, we placed the center of the error ellipse at this middle point (given in 'table 2) and adopted the following semi-major and semi-minor axes:

$$\begin{cases} a = 0.20 + r_s, \\ b = 0.10 + r_s, \end{cases} \quad (4)$$

where, on the right-hand side of eq. (4), θ is the angular separation between the two radio lobes, given in Table 2; and r_s , given in eq. (3), is usually much smaller than the first term. Finally, for R230, which was not detected at 4.86 GHz, we simply used a large searching radius of $15''$.

4.4. The Results

Optical identification was carried out on all the R-band CCD images. The results are summarized in Table 3 which contains, for each source, the following data columns:

Columns (2) to (4) are data related to the whole CCD image, where column (2) identifies the date of observation (UT); column (3) gives the FWHM of the optical seeing in units of arcseconds; and column (4) gives $N^{23.5}_{\text{opt}}$, the number of the detected optical objects with $R < 23.5$ mag. Note that $N^{23.5}_{\text{opt}}$ is not given for three CCD fields that contain "bleeded" images of bright stars.

Astrometric data are given in columns (5) to (8) of Table 3. The semi-major and semi-minor axes of the adopted error ellipse are given in units of seconds of arc in column (5) while its position angle (north to east) in degrees is in column (6). Columns (7) and (8) are the positional offsets in the R.A. and decl. directions, respectively, measured in units of seconds of arc from the radio position to the position of an optical identification.

For faint optical identifications, we give in columns (9) to (10) the offsets in units of arcseconds in the R.A. and decl. directions from a nearby bright star to the optical identification. The approximate R magnitude of this offsetting star is given in column (11).

Columns (12) to (16) of Table 3 are photometric data on each optical counterpart. Column (12) differentiates between a point source (QSO) and an extended source (Gal) based on the point spread function in the CCD field. Column (13) is the I-OCAS-measured

isophotal magnitude. For a split object, this magnitude is given by eq. (1). If there are multiple identifications, the brightest one is usually taken to be the most probable optical identification and is listed first in Table 3. Column (14) is the isophotal area in units of arcsec², determined by eq. (2). For each optical identification, its major and minor diameters in units of arcseconds are given in column (15) and its position angle (north to east) in degrees in column (16). These were derived from the following parameters:

$$\tan(2\beta) = \frac{2 \langle xy \rangle}{\langle x^2 \rangle - \langle y^2 \rangle}, \quad (5a)$$

$$r_p^2 = \langle x^2 \rangle \cos^2 \beta + \langle y^2 \rangle \sin^2 \beta + \sin(2\beta) \langle xy \rangle, \quad (5b)$$

and

$$r_m^2 = \langle x^2 \rangle \sin^2 \beta + \langle y^2 \rangle \cos^2 \beta - \sin(2\beta) \langle xy \rangle. \quad (5c)$$

in the above formula, $\langle x^2 \rangle$, $\langle y^2 \rangle$ and $\langle xy \rangle$ are the (unweighted) 2nd moments evaluated within the FOCAS isophotal area; β and r_p^2 are, respectively, the angle of the major or minor axis with respect to the x-axis and the second moment evaluated along this axis; and r_m^2 is the second moment evaluated along the other axis. For an isolated object, its major and minor diameters were given, respectively, by

$$2a = \max(2\sqrt{r_p^2}, 2\sqrt{r_m^2}) \quad (6a)$$

and

$$2b = \min(2\sqrt{r_p^2}, 2\sqrt{r_m^2}), \quad (6b)$$

and finally its position angle was determined. For a split object, the diameters given by eqs. (6) were multiplied further by $(A_{\text{iso}}^c/A_{\text{iso}}^{\text{focas}})^{1/2}$ to derive the *fills* diameters listed in Table 3, where A_{iso}^c and $A_{\text{iso}}^{\text{focas}}$ are, respectively, the ‘‘corrected’’ (by eq. [2]) and 1-FOCAS-measured isophotal areas.

Of the 42 optically observed DS sources, 37 (88%) were optically identified. These include (i) 34 sources with unique optical identifications and (ii) 3 sources (1014, R080,

and R276) with two optical objects within their searching ellipses. For group (i), the optical counterparts are mostly within $2''$ of the radio positions. Based on the average surface density of the detected objects in our CCD fields and a Poisson fluctuation, the chance for an unrelated background object of $R \lesssim 24$ mag to be within $1''.5$ of the radio source position is about 3%. This suggests that one out of the 34 optical identifications may be false. Since many of the optical counterparts are much brighter than $R = 24$ mag, the number of false identifications is probably much less than one. The same arguments led us to believe that a few radio sources, as already specified in §2, actually consist of two independent sources each with an identified optical counterpart. For group (ii), the optically brighter one was taken to be the most probable optical counterpart and used in the statistical analysis below. The chance for a false identification is still quite low here, except for R080, which has two possible faint optical counterparts.

For the observed NS sources, one source (R139) turned out to be a galaxy of $R \gtrsim 20$ mag. The remaining NS sources all have an identification of $15.5 < R < 18.5$ mag, in agreement with CDS90 identification.

We display the *i*-band CCD images of the observed radio fields in Fig. 5. In each image we have marked each optical counterpart if the radio source was identified or the radio position if it was unidentified. For optically faint radio sources, the offsetting stars given in Table 3 for positional offsets are also marked in Fig. 5.

5. Statistical Properties: The Distant Sample

5.1. Radio Angular Sizes and Spectral Indices

Radio data at 4.86 GHz were obtained for all DS sources but two (R262 and R353). The distribution of the (maximum) angular sizes at 4.86 GHz, θ , for the DS sources is

shown in Fig. 6 (unhatched histogram), where in addition, the hatched histogram represents the subset of sources with $\theta \gtrsim 11''$ and FR II radio morphology (including two with FR 1/11). It is clear that the majority of these fully resolved DS sources have FR II radio morphology. Together with the sample characteristic flux density, this suggests that most of these sources are likely at high redshifts.

The distribution of the radio spectral indices, α , is shown in Fig. 7 for two subsamples divided by $\theta \approx 5''$. All but one DS sources with $\theta \gtrsim 5''$ are ‘(steep spectrum” sources with $\alpha > 0.55$ and their Gaussian-like distribution of α has a mean of 0.95 and a standard deviation of 0.20. In contrast, about 40% (10 in number) of the sources with $\theta \lesssim 5''$ (all arc unresolved) are ‘flat-spectrum” sources with $\alpha < 0.55$. The fact that all these flat-spectrum sources are unresolved implies that their physical sizes must be relatively compact. Overall, our distant radio sample contains roughly 80% steep-spectrum, extended sources and 20% flat-spectrum, compact sources.

5.2, Optical Characteristics

The majority of optical counterparts appear to be extended galaxies with elliptical isophotes, consistent with existing findings in samples at similar flux levels (e.g., Windhorst et al. 1985). As noted in Table 3, five of the 37 optically identified DS sources are possibly QSOS with a point-source like image. If none of them are Galactic stars, this suggests a QSO fraction of $14\% \pm 6\%$ in the distant sample. This rate is slightly lower than the average QSO fractions of 20% to 25% found in the 3CR catalog (Laing et al. 1983), the 1-Jy sample (Allington-Smith et al. 1982), and a radio sample that is even fainter than our 1J (Kron, Koo, & Windhorst 1985). A revised estimate of this QSO fraction will be given when we have optical colors or spectra.

The unhatched histogram in Fig. 8a shows the R magnitude distribution for all the 37 identified DS sources, while the hatched part of the histogram represents the 5 possible QSOs. The flat-spectrum sources all have $R < 21$ mag, brighter on average than those with steeper radio spectra.

Of the 5 unidentified DS sources, one ($R \approx 21.5$) is probably fainter than our detection limit. The CCD images of the remaining 4 sources have a value of $N_{\text{opt}}^{23.5}$ that is, on average, 100 counts less than that of a CCD field taken under a good weather (see Fig. 4). Together with Fig. 3a, this suggests that these sources should be at least fainter than about 21.5 mag in R .

5.3. On Redshifts and Radio Luminosities

Spectroscopic redshift data for most DS sources are not yet available at the time of writing this paper. But some order-of-magnitude estimates could be made on the basis of their optical morphology and R magnitudes. Fig. 8b plots redshifts versus R magnitudes for the 3CR (Spinrad et al. 1985) and 1-Jy radio sources (Allington-Smith 1984; Allington-Smith, Lilly & Longair 1985; Lilly 1989) with spectroscopic redshifts, represented by triangles and circles, respectively. The symbols for known QSOs are darkened in the figure in order to be differentiated from radio galaxies. For the 3CR sources, their R magnitudes were derived from the available V magnitudes in Spinrad et al. (1985) by simply assuming $(V - R) = 1$ mag, a rough average color as implicitly suggested by the colors tabulated in Laing et al. (1983). The same average $(V - R)$ color was assumed for some 1-Jy sources whose V magnitudes are given in Lilly (1989). In spite of the fact that the optical magnitudes used here are quite nonuniform and of various accuracies, the two plotted parameters show a fairly good correlation for radio galaxies. A comparison between Figures 8a and 8b would imply that most of the optically identified DS sources with $R \gtrsim 20$

mag should have $0.8 \lesssim z < 4$ if the correlation in Fig. 8b is largely independent of radio powers. The above upper limit in redshift is very 100SC given the uncertainties in, e.g., the K-correction, and inevitable evolution effect. On the other hand, most of the optical luminosity of a radio galaxy could be triggered by radio activities at high redshifts, $z \gtrsim 1$ (e.g., Chambers & Chariot 1990). In this case the R-band optical luminosity could scale as $P_{1.4}^{0.6}$, where $P_{1.4}$ is the radio power at 1.4 GHz (Chokshi & Eisenhardt 1991; see also Auriemma et al. 1977 for earlier work on the bivariate radio-optical luminosity function). Being 45 times weaker than the 3CR sources in radio, our DS sources would be about 2 magnitude fainter in the R-band than the 3CR sources at a given high redshift and would only reach up to $z \sim 1.5$ or so. Of course, the reality could well be somewhere between these two extremes. Nevertheless, a significant fraction of the DS sources should have $z \sim 1$ or $P_{1.4} \sim 1026 \text{ W Hz}^{-1}$, making them typical FR II-type radio sources.

5.4. Alignment between Optical and Radio Images

Most powerful radio galaxies at $z \sim 1$ show some tendency for their radio axes to be aligned with the optical or near-IR major axes of the underlying galaxies (e.g., McCarthy et al. 1987; Eisenhardt & Chokshi 1990; Rigler et al. 1992). However, whether such optical-radio alignment phenomenon depends strongly on radio power has to be tested by using samples of lower-power radio galaxies at high redshifts. Insignificant or much weaker optical-radio alignment was found for some weaker radio galaxies at high redshifts by Dunlop & Peacock (1993) using the Parkes survey and by Thompson et al. (1994) using the B3 survey.

For 24 optically identified radio sources that are partially or fully resolved at 4.86 GHz (i.e., $\theta \gtrsim 5''$), we plot in Fig. 9 the distribution of the angles, $\delta(PA)$, between the optical and radio major axes of each source. There is an apparent tendency for the two axes to be

within about 20° of either parallel or perpendicular to each other, but only at a significance of $\lesssim 2\sigma$ (assuming Poisson statistics). The significance for $\delta(PA)$ to be within 20° of zero is only about 1 σ . We therefore conclude that our data do not show any evidence for a tendency of the optical and radio axes to be aligned with each other.

5.5. Radio Source Environments

The environments of radio galaxies in the local universe (e.g., $z \lesssim 0.2$) are correlated with radio powers, in the sense that low-power, FR I sources tend to be in rich clusters while the powerful, FR II radio sources usually lie in the field or in galaxy groups (e.g., Longair & Seldner 1979; Prestage & Peacock 1988). Clustering analysis has been recently extended to radio galaxies around $z \sim 0.5$ by Yates, Miller, & Peacock (1989) using 3CR radio galaxies of Cygnus A type and by Hill & Lilly (1991) using radio galaxies of both FR types. Both studies found positive evidence for $z \sim 0.5$ radio galaxies to have at least an equal probability to be found in clusters as in the field. However, the least well sampled part of the radio luminosity function at $z \sim 0.5$ in the above two studies is around a radio power of $P_{1.4} \sim 10^{26} \text{ W Hz}^{-1}$ where most nearby FR II radio galaxies (mostly from the 3CR) lie.

Even without spectroscopic redshift data, we have some statistical inferences on the average environments of our DS radio sources. To extract an optically uniform subsample for this purpose, we have selected only those DS sources that satisfy (1) $18 < R \lesssim 21.5$ mag, (2) the optical seeing $< 2''$, and (3) $N_{\text{opt}}^{23.5} > 150$. For each selected source, we calculated the following quantity:

$$\Delta N(R_1, R_2, r_1, r_2) \equiv N_{\text{opt}}(R_1 < R < R_2; r < r_1) - N_{\text{opt}}(R_1 < R < R_2; r_1 < r < r_2), \quad (7)$$

where $N_{\text{opt}}(R_1 < R < R_2; r_1 < r < r_2)$ is the number of the detected optical objects (including the radio source itself if geometrically appropriate) that have an R-band

magnitude between R_1 and R_2 and lie between radii of r_1 and r_2 of the center of the CCJ) field (near which the radio source lies). Thus, ΔN in eq. (7) measures the magnitude-limited excess of number counts within the inner radius r_1 over that in the annulus delimited by radii r_1 and r_2 .

We note that the angular size of a given metric length does not vary much between $z \sim 1$ and 2 (e.g., Weedman 1986, p. 66). We further divided the above selected sources into two subsamples in terms of the estimated redshifts from Fig. 8: a subsample of 11 sources with $20 < R \lesssim 21.5$ mag (or likely to have $0.8 \lesssim z \lesssim 1.5$) and a subsample of 4 sources with $18 < R < 20$ mag (or roughly $0.3 \lesssim z \lesssim 0.8$). We shall refer to these two subsamples as 1)S1 and DS2, respectively. For simplicity, we assigned a redshift of unity to every DS1 source and a redshift of 0.5 to every DS2 source. Furthermore, we chose $r_1 = 75''$ and $r_2 = 106''$ for the DS1 sources, and $r_1 = 90''$ and $r_2 = 127''$ for the 1)S2 sources. Assuming $q_0 = 0.5$ and $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$, for a given metric length, the ratio of its angular size at $z = 0.5$ to that at a redshift between 1 and 2 is about 1.2 and an angular size of $75''$ corresponds to 0.43 Mpc at $z \sim 1.0$ (e.g., Weedman 1986, p. 66). Thus, the above choice of r_1 and r_2 implies that we are sampling roughly the same metric area for both subsamples, and that the linear size of r_1 corresponds to about 2.5 cluster core radii at which the projected galaxy density of a typical cluster falls to $\sim 8\%$ of the central peak density (e.g., Bahcall 1975).

As we will show in the next section, at least three of the five radio sources, which lie within $40''$ of the nominal center of some galaxy clusters in Gunn et al. (1986), are very likely to be the first ranked cluster galaxies. These clusters have a spectroscopic or estimated redshift around $z \sim 0.5$ (Gunn et al. 1986; Dressler & Gunn 1992) and have richnesses ranging from being very rich (i.e., Abell 851 around R082) to an Abell richness 1 or so. Having $18 < R < 20$ mag and passing the same selection criteria as the 1)S1 and 1)S2, these 5 sources constitute a third subsample (hereafter, referred to as NSal),

for which we also used $z = 0.5$, $r_1 = 90''$ and $r_2 = 127''$. Table 4 lists all the three subsamples with the following parameters: Column (2) lists the sources in each subsample. Column (3) gives the (sub) sample median or mean and the range of R-band magnitudes in each subsample. Columns (4) and (5) have similar formats as Column (3), but for $S_{1.4}$ and $\log P_{1.4}$, respectively. The *rest-frame* radio power at 1.4 GHz, $P_{1.4}$, was calculated using the assumed redshift for each subsample, $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $q_0 = 0.5$ and a spectral index of $\alpha = 0.9$. We used medians for DS1 but means for the other two subsamples of smaller sizes. It is clear that the median power of the DS1 is around $10^{26} \text{ W Hz}^{-1}$, the typical power of nearby FR II-type radio galaxies in the 3CR catalog.

Fig. 10 shows the distribution of ΔN of each subsample in Table 4, where the hatched histogram represents $\Delta N(R_{\text{radio}}, R_{\text{radio}} + 2, r_1, r_2)$ and the unhatched, thick solid histogram represents $\Delta N(R_{\text{radio}} - 1, R_{\text{radio}} + 1, r_1, r_2)$, with R_{radio} being the optical R magnitude of the radio source under consideration. Note that $R_{\text{radio}} + 2 < 23.5$, the limiting magnitude for our optical CCD catalogs. Recent CCD surface photometry of nearby radio galaxies indicated that on average, the host galaxies of FR I radio sources are probably 1 mag brighter than the host galaxies of FR II radio sources (Owen & White 1991). If this is also the case at high redshifts, the unhatched histograms of the DS1 and DS2, which contains mainly FR II sources, should be compared with the hatched histogram of the FR I-type radio sources in the NSal.

The sample mean value of $\Delta N(R_{\text{radio}}, R_{\text{radio}} + 2, r_1, r_2)$ and its standard deviation, derived from the sample mean value of $N_{\text{opt}}(R_{\text{radio}} < R < R_{\text{radio}} + 2; r < r_1)$ using Poisson statistics, are given in column (6) of Table 4. For the NSal sources, the value of ΔN is clearly correlated with the richness of the cluster: from a value of 3 to 4 for R191 and R252 which may or may not be physically in clusters (see §6), to around 15 for the richest cluster around R082. The sample mean of AAT is 8 ± 2.9 . On the other hand, as shown in Table 4,

the mean of AN for the DS 1 sources using either the hatched or unhatched histogram is essentially zero, suggesting either that there is no significant clustering (i.e., much less than Abell richness 1) around these sources on average or that most DS1 sources are primarily on the outer parts of a cluster (i.e., $\gtrsim 3$ cluster core radii). The situation of the DS2 sources are intermediate with an mean of $\Delta N \lesssim 3 \pm 2.4$.

6. Statistical Properties: The Nearby Sample

Of the 36 NS sources, seventeen were included in both our 4.86GHz VLA snapshot and R-band CCD imaging observations. One (R139) turned out to have $R \approx 20.3$ mag which is much fainter than the limiting magnitude of the NS. We shall not discuss this galaxy further here. Fig. 11 plots the CCD R magnitude as a function of $\log D_{65\%}^r$, the logarithmic diameter measured on the red POSS plate at 65% plate transmission in CDS90 (roughly at a surface brightness of 24 mag arcsec² in red), for all the NS sources with CCD images except for R160 (a quasar) and R201 for which its close, equally-bright companion makes $D_{65\%}^r$ uncertain. While deferring a detailed photometric calibration on POSS galaxies (both the optical counterparts of the NS radio sources and other optical galaxies) to a future paper in which we will compare our NS radio sources with a sample of radio sources in rich superclusters of galaxies at $z \sim 0.1$, we derive here a crude photometric calibration for the NS sources without CCD measurements. We have simply fitted two linear relations to the points in Fig. 11 and adopted the following fit:

$$R = \begin{cases} (27 - 5 \log D_{65\%}^r) & \text{if } \log D_{65\%}^r \geq 2, \\ 17 + 0.6[(27 - 5 \log D_{65\%}^r) - 17] & \text{otherwise.} \end{cases} \quad (8)$$

The fit results in an rms residual of ~ 0.3 mag. Eq.(8) was used to show, in Fig. (12), the magnitude distribution for all our NS sources. The hatched histogram in Fig. (12) singles out the subset of 16 sources with CCD magnitudes. The two optically brightest sources are

nearby spiral galaxies: R043 (UGC 05157; $R \sim 12.9$ mag and $z \approx 0.016$) and R213 (UGC 05263; $R \sim 13.7$ mag). Thus, we start to sample low-radio power spiral galaxies at $R \lesssim 15$. For $R > 15.5$, all the sources with CCD images appear to be normal elliptical galaxies except for R133 and R160. R133 has an impressive point source-like nucleus surrounded by vigorous spiral arms and, therefore, resembles the so-called N-galaxy. R160 has been confirmed to be a QSO based on our spectroscopic observations (Huchra et al. 1995). Fig. 12 also shows that the subsample of the 16 NS sources included in our VLA and optical CCD observations is fairly representative of the total NS sample for $R \gtrsim 15.5$ mag. Consequently, we only discuss the statistical properties of this subsample below.

The spectral indices of the NS sources range from 0 to 1.2 and have a mean around 0.7. The distribution of the 4.86 GHz radio sizes span up to $\sim 20''$, with 53% of the sources being unresolved (i.e., $\theta \lesssim 5''$).

While our particular sample selection on the sky implies that most of the NS sources are not in clusters, we found that most of them have close companions. Except for R160 (QSO), R247 and R281, all of the remaining NS sources have, within a radius of $15''$, a companion with a magnitude neither brighter nor more than 3 mag fainter than the radio source. This separation corresponds to a linear size of $\lesssim 50$ kpc even at $z \sim 0.5$ ($H_0 \sim 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$). We show in Fig. 13 the variations of the surface density of the detected optical objects (excluding the radio source itself) as a function of the radial distance from the radio source. Only optical objects with an R magnitude between R_{radio} and $(R_{\text{radio}} + 4)$ were used. Shown in Fig. 13 are three sets of radio sources: (a) the 5 sources with $18 < R < 19.5$ mag that are near some known clusters, of which three (R082, R191 and R252) are NS sources; (b) five NS sources with $17 < R < 18.5$ mag, not including any NS source in (a); and (c) six NS sources with $15.5 < R < 17$ mag. Three of the 5 sources in (a) including the NS source R082 and two additional NS sources, R212 and R239,

in (b) have similar radial profiles that fall slowly even at our sampled radii, making them all characteristic of cluster sources. On the other hand, the other two NS sources in (a), R191 and R252, may not be physically associated with clusters at all as their curves, like those of the NS sources with $15.5 < R < 17$ mag, have negligible slopes beyond a radial distance of 40" to 60". We summarize our findings as follows: Most of the NS radio sources with $R < 17$ mag (or roughly $z \lesssim 0.2$) have excess companions only within a radius of $\sim 50''$, making their environments typical of galaxy groups; for $17 < R \lesssim 19$ mag (or roughly $0.2 < z \lesssim 0.5$), about 40% of the NS sources are in clusters, 50% are in groups, and 10% are in the field.

7. Summary

From the 1.4 GHz radio survey of Condon, Dickey, & Salpeter (1990) in a region much devoid of rich galaxy clusters at $z \lesssim 0.4$, we selected two subsamples: (1) a "distant" sample, DS (or "optically faint"), namely, all the 57 radio sources which have 1.4 GHz flux density of 35 mJy or more, irrespective of optical magnitudes; and (2) a "nearby sample", NS (or "optically bright"), namely all the radio sources in the original survey, irrespective of radio flux, which are optically brighter than $B \sim 19$ mag. These include two sources in common. Our ultimate goals are (a) to study the radio, optical and near-IR properties of those high-redshift ($z \sim 1$), moderate-power radio sources in the distant sample and to compare them with that of more powerful radio sources, and (b) to make a comparison of primarily non-cluster radio sources in the nearby sample with a companion survey of radio sources in a pair of rich superclusters at $z \sim 0.1$. In this first paper, we report our new C-array VLA continuum snapshots at 4.86 GHz and optical R-band CCD imaging photometry for these two samples and tabulate the observational results on individual sources.

We hope to collect more redshift data for our sources, which will be needed for

unambiguous interpretations. However, we have almost complete optical identifications for our two samples (i.e., apparent magnitudes) and radio spectral indices, so some statistical properties are already known. These can be summarized as follows. (1) The distant sample: (a) The majority (80%) of the sample sources have a steep spectrum between 1.4 and 4.86 GHz with a spectral index around 0.9. Nineteen (90%) of the 21 sources that are fully resolved at 4.86 GHz (i.e., angular sizes $\theta \gtrsim 11''$) have a radio morphology of Fanaroff-Riley (FR) II type. (b) Thirty-seven (88%) of the 42 optically imaged sample sources were identified to a limiting R-band magnitude of $R \sim 23.5$ mag. About 15% of the identified radio sources appear to be point sources and the others are extended galaxies with an appearance similar to nearby elliptical galaxies. (c) Twenty-eight (76%) of the optically identified sources have $R > 20$ mag, suggesting that these are probably distant ($z \gtrsim 0.8$), with a redshift distribution peaking at $z \sim 1$ where their radio luminosities are about 10 times the break power between the FR I and 1 I classes. (d) We found no strong evidence for the radio and optical axes of the resolved radio sources (i.e., $\theta \gtrsim 5''$) to be correlated or anti-correlated, nor any evidence for strong clustering around sample radio sources on average. (e) The median 1.4 GHz flux density for the distant sample as a whole is about 65 mJy and the median red apparent magnitude is about 21.0 mag, compared with about 2820 mJy and 17.5 mag for the 3CR sample (see Spinrad et al. 1985) and about 490 mJy and 20.2 mag for the "1-Jy" sample of Allington-Smith (1982). (2) The nearby sample: Except for $R \lesssim 15$, the sample is dominated by elliptical galaxies with $16 \lesssim R < 18.5$ mag and a spectral index distribution similar to that of the distant sample. Based on the radial distribution of optical objects around each radio source, we found that the average radio source environment becomes richer from that characteristic of galaxy groups for $R < 17$ mag (roughly $z \lesssim 0.2$) to that of galaxy groups to clusters at $R \gtrsim 18$ mag (roughly $z \gtrsim 0.3$).

We are grateful to the staffs of both Palomar Observatory and VLA for their help in our

observations, to N. Rowlands for helping us with some of the CCD imaging observations, to J. Dickey for providing us with a catalog of stars generated from Minnesota Automatic Plate Scanner, to F. Valdes for helps on installing and running the FOCAS, to M. Dickinson for providing us with a machine-readable 3CR catalog, to K. Zadorozny for making the radio contour plots, to P. Eisenhardt for many enlightening discussions, to J. Condon, J. Huchra, O. Liivak, P. McCarthy, R. Windhorst for helpful conversations, and to the referee of this paper. This work was supported in part by the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration, by NSF grants AST91-19475 at Cornell University, by NSF grants AST-9015181 and AST-9316213 at Lafayette College, and by the National Radio Astronomy Observatory which is operated by the Associated Universities Inc. under a cooperative agreement with the National Science Foundation.

A. Conversion of CDS90 Positions to the 11ST Guide Star Catalog (GSC) System

We found a total of 53 stars in common between the CDS90 and GSC catalogs, and show in Fig. 14 the R.A. and decl. differences between these two systems. It is evident that $\Delta(\alpha)$, which $\equiv \alpha(\text{CDS90}) - \alpha(\text{GSC})$, has a dependence on δ ; and $\Delta(\delta)$, which $\equiv \delta(\text{CDS90}) - \delta(\text{GSC})$, depends on both α and δ . For simplicity, we have least-squares fit $\Delta(\alpha)$ to a linear function of δ and A(6) to a linear combination of α and δ . The results are

$$\Delta(\alpha) = 1.47(\delta - 47.4^\circ) + 0.23 \quad (9)$$

and

$$\Delta(\delta) = 7.24(\alpha - 9.75^{\text{h}}) + 0.83(\delta - 47.4^\circ) - 1.44, \quad (10)$$

where α and δ are in units of hours and degrees, respectively; and $\Delta(\alpha)$ and A(6) are in units of arcseconds. These fits are sufficient in the sense that they take away almost all the observed correlations in Fig. 14. After converting the CDS90 positions to the GSC scale using eqs. (9) and (10), the rms values for $\Delta(\alpha)$ and A(δ) arc, respectively, 0".88 and 0".94, in agreement with the random error estimates.

Figure Captions

Fig. 1.-- Integral distribution of the DS sample sources in terms of radio flux density, $S_{1.4}$, at 1.4 GHz. The error bars represent 1σ (Poisson) and the dashed line with a slope of $-\frac{3}{2}$ for $S_{1.4} > 35$ mJy is a nominal fit to the data points except the two with the largest flux densities.

Fig. 2.-- Radio continuum contour plots from the VLA C-array snapshots at 4.86GHz. North is at the top and east is to the left. Shown in the lower right corner of each plot is the $4''.2$ VLA synthesized beam which also serves as a rough indicator of the size of the plot. The contour levels are marked at the lower left corner of each plot as follows: a general notation '5 x 2' means that the lowest contour is 5 mJy beam⁻¹ and that the others follow in multiples of 2 (i.e., 5, 10, 20, etc.); but for some cases we used a notation such as "5, 8, 13" to indicate the actual contour levels in mJy beam⁻¹.

Fig. 3.-- Plots of FOCAS originally detected objects from a typical R-band CCD image (R035 in this case with an optical seeing of $\sim 1''.5$): (a) distribution of the isophotal magnitudes, R_{iso} , where the error bar represents 1σ and the dashed curve is the expected number counts from field galaxies (from Tyson 1988) and stars (from Bahcall & Soneira 1984b; see the text for more explanation); (b) plot of the total magnitude, R_{tot} , as a function of R_{iso} , where the diagonal line indicates where $R_{tot} = R_{iso}$; (c) same as (b), but the ordinate is now the logarithmic isophotal area A_{iso} . These plots change only a little if objects obtained after FOCAS splitting procedure are used instead.

Fig. 4.-- Plot of the number of the detected optical objects with $R < 23.5$ mag in a CCD field as a function of the FWHM of the optical seeing when that CCD image was taken. The circles are for the DS sources and squares are for the NS and additional sources. The 5 sources that are close to some known galaxy clusters have their square symbols filled (one

of them, R082, with $N_{\text{opt}} = 453$ and an optical seeing of $1''.6$, is off the scale), as do the 5 DS sources that are not optically identified in this paper.

Fig. 5.-- R-band CCD images of the observed radio sources. Each CCD field covers an area of about $4'.2 \times 4'.2$. North is at the top and east to the left. The two solid lines bisect the optical identification of the radio source or the radio source position in the case where no optical counterpart was identified. The single solid line points to the offset star listed in Table 3. Additional "blow-up" images of $30'' \times 30''$ are shown for R124, R212, R216, R239 and R304 which all have close objects.

Fig. 6.-- The unhatched histogram represents the distribution of the (maximum) angular sizes, θ , for all the 1)S sources, while the hatched histogram is for the subset of sources with $\theta \gtrsim 11''$ that show a FR II radio morphology on our VLA snapshots at 4.86GHz.

Fig. 7.-- Distributions of the spectral indices, α , between 1.4 and 4.86 GHz for two DS subsamples: (a) 24 sources with a (maximum) angular size, θ , less than about $5''$, and (b) the remaining 31 1)S sources with $\theta > 5''$.

Fig. 8.— (a) The unhatched histogram shows the R magnitude distribution for all 37 DS sources that have been optically identified in this paper. The part of the histogram for the 5 possible QSOS is hatched. (b) Plot of spectroscopic redshifts vs. R magnitudes for the 3CR (triangles) and 1-Jy radio sources (circles). The symbols for known QSOS are filled.

Fig. 9.— Distribution of the position-angle differences (limited to between 0° and 90°) between the radio sources and their optical counterparts for the 24 optically identified 1)S sources that are at least partially resolved (i.e., with a maximum angular size $\gtrsim 5''$) on our 4.86GHz snapshots. The dashed line shows the expected mean from a random distribution.

Fig. 10--- Histogram distributions of AN, defined in eq. (7) in the text, for three subsamples: (a) DS1 -11 DS radio sources with $20 < R \lesssim 21.5$ mag, (b) DS2 --4 DS radio sources with $18 < R < 20$ mag, and (c) NSal -- the five radio sources near some known galaxy clusters. The hatched histograms are for $\Delta N(R_{\text{radio}}, R_{\text{radio}} + 2, r_1, r_2)$ and the unhatched, thick solid histograms are for $\Delta N(R_{\text{radio}} - 1, R_{\text{radio}} + 1, r_1, r_2)$, Where R_{radio} is the R magnitude of the radio source under consideration, $r_1 = 75''$ ($90''$) and $r_2 = 106''$ ($127''$) for DS1 (1)S2 and NSal) sources. The value of AN measures the magnitude-limited excess of number counts within the inner radius r_1 over that in the annulus delimited by radii r_1 and r_2 .

Fig. 11---- Plot of CCD R magnitudes vs. $(27 - 5 \log D_{65\%}^r)$ for the 14 NS sources with available CCD magnitudes. $D_{65\%}^r$ is the diameter, in units of microns, measured on the red POSS plate at 65% plate transmission in CDS90 (roughly at the 24th mag arcsec⁻² in red). The solid lines represent eq. (8), a simplified least-squares fit to the data.

Fig. 12.--- R-band magnitude distribution of all the NS sources. The hatched part represents those with available CCD magnitudes. The magnitudes of sources without CCD magnitudes were estimated using eq. (8).

Fig. 13.--- Variations of the surface density of optical objects (excluding the radio source itself) as a function of the radial distance from the radio source for three data sets: (a) the 5 sources with $18 < R < 19.5$ mag that are near some known clusters, including 3 NS sources; (b) five NS sources with $17 < R < 18.5$ mag, not including any NS source in (a); and (c) six NS sources with $15.5 < R < 17$ mag. Only optical objects with an R magnitude between R_{radio} and $R_{\text{radio}} + 4$ were used, where R_{radio} is the magnitude of the radio source.

Fig. 14.- Positional differences in Equatorial Coordinates between the CDS90 and the 11ST GSC systems for 53 stars in common: (a) $\alpha(\text{CDS90}) - \alpha(\text{GSC})$ vs. α , (b) $\alpha(\text{CDS90}) - \alpha(\text{GSC})$ vs. δ , (c) $\delta(\text{CDS90}) - \delta(\text{GSC})$ vs. α , and (d) $\delta(\text{CDS90}) - \delta(\text{GSC})$ vs. δ .

^aRadio signals are weak.

^bRadio signals are weak. Only the two largest components are listed, i.e., the one on the most left and the one in the middle of the radio contour plot in Figure 2.

^cRadio signals are weak. The two components of R203 are shown separately in Figure 2 as R203A and R203B. The objects are at the center of each plot.

^dNot detected. Uppers limits are 3σ .

^aThe optical counterpart lies slightly outside the error ellipse. It was accepted for either it is optically bright with a radius *much* larger than its apparent angular distance to the radio source position or it is well between the two radio lobes.

^bThe integration time for the R-band CCD image is only 300 seconds.

^cR082 is in a very dense galaxy cluster at $z = 0.407$ (Dressier & Gunn 1992). The magnitude may be slightly contaminated.

^dThere is an optical object near one of the radio components.

^eThis optical identification is slightly outside the error ellipse. It was accepted because the central position of this weak radio source is somewhat uncertain.

^fRadio map at 4.86GHz is not available. The offsets [i.e., cols. (7) and (8)] for the second probable optical counterpart are with respect to the optics! position of the first one.
